# Lecture 3: Linear Models

Bruce Walsh lecture notes
Uppsala EQG course
version 28 Jan 2012

## Quick Review of the Major Points

The general linear model can be written as

$$y = X\beta + e$$

- y = vector of observed dependent values
- X = Design matrix: observations of the variables in the assumed linear model
- $\beta$  = vector of unknown parameters to estimate
- e = vector of residuals (deviation from model fit), e = y-X  $\beta$

$$y = X\beta + e$$

Solution to  $\beta$  depends on the <u>covariance structure</u> (= covariance matrix) of the vector **e** of residuals

### Ordinary least squares (OLS)

- OLS:  $e \sim MVN(0, \sigma^2 I)$
- Residuals are homoscedastic and uncorrelated, so that we can write the cov matrix of  $\mathbf{e}$  as  $Cov(\mathbf{e}) = \sigma^2 \mathbf{I}$
- the OLS estimate,  $OLS(\beta) = (X^TX)^{-1} X^Ty$

### Generalized least squares (GLS)

- GLS: e ~ MVN(0, V)
- · Residuals are heteroscedastic and/or dependent,
- $GLS(\beta) = (X^T V^{-1} X)^{-1} V^{-1} X^T y$

## BLUE

- Both the OLS and GLS solutions are also called the Best Linear Unbiased Estimator (or BLUE for short)
- Whether the OLS or GLS form is used depends on the assumed covariance structure for the residuals
  - Special case of  $Var(e) = \sigma_e^2 I -- OLS$
  - All others, i.e., Var(e) = R -- GLS

## Linear Models

One tries to explain a dependent variable y as a linear function of a number of independent (or predictor) variables.

A multiple regression is a typical linear model,

$$y = \mu + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_n x_n + e$$

Here e is the **residual**, or deviation between the true value observed and the value predicted by the linear model.

The (partial) regression coefficients are interpreted as follows. A unit change in  $x_i$  while holding all other variables constant results in a change of  $\beta_i$  in y

## Linear Models

As with a univariate regression (y = a + bx + e), the model parameters are typically chosen by least squares, wherein they are chosen to minimize the sum of squared residuals,  $\Sigma$   $e_i^2$ 

This unweighted sum of squared residuals assumes an OLS error structure, so all residuals are equally weighted (homoscedastic) and uncorrelated

If the residuals differ in variances and/or some are correlated (GLS conditions), then we need to minimize the weighted sum  $e^TV^{-1}e$ , which removes correlations and gives all residuals equal variance.

### Predictor and Indicator Variables

Suppose we measuring the offspring of p sires. One linear model would be

$$y_{ij} = \mu + s_i + e_{ij}$$

 $y_{ij}$  = trait value of offspring j from sire i  $\mu$  = overall mean. This term is included to give the  $s_i$  terms a mean value of zero, i.e., they are expressed as deviations from the mean

 $s_i$  = The effect for sire i (the mean of its offspring). Recall that variance in the  $s_i$  estimates Cov(half sibs) =  $V_A/4$ 

 $e_{ij}$  = The deviation of the jth offspring from the family mean of sire i. The variance of the e's estimates the within-family variance.

## Predictor and Indicator Variables

In a regression, the predictor variables are typically continuous, although they need not be.

$$y_{ij} = \mu + s_i + e_{ij}$$

Note that the predictor variables here are the  $s_i$ , (the value associated with sire i) something that we are trying to estimate

We can write this in linear model form by using indicator variables

$$x_{ik} = \begin{cases} 1 & \text{if sire } k = i \\ 0 & \text{otherwise} \end{cases}$$

Models consisting entirely of indicator variables are typically called ANOVA, or analysis of variance models

Models that contain no indicator variables (other than for the mean), but rather consist of observed value of continuous or discrete values are typically called regression models

Both are special cases of the General Linear Model (or GLM)

$$y_{ijk} = \mu + s_i + d_{ij} + \beta x_{ijk} + e_{ijk}$$

Example: Nested half sib/full sib design with an age correction  $\beta$  on the trait

Example: Nested half sib/full sib design with an age correction  $\beta$  on the trait

## ANOVA model

$$y_{ijk} = \mu + s_i + d_{ij} + \beta x_{ijk} + e_{ijk}$$

### Regression model

 $s_i$  = effect of sire i  $d_{ij}$  = effect of dam j crossed to sire i  $x_{iik}$  = age of the kth offspring from i x j cross

## Linear Models in Matrix Form

Suppose we have 3 variables in a multiple regression, with four (y,x) vectors of observations.

$$y_i = \mu + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + e_i$$

In matrix form,  $y = X\beta + e$ 

$$\mathbf{y} = \begin{pmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{pmatrix} \quad \boldsymbol{\beta} = \begin{pmatrix} \mu \\ \beta_1 \\ \beta_2 \\ \beta_3 \end{pmatrix} \quad \mathbf{X} = \begin{pmatrix} 1 & x_{11} & x_{12} & x_{13} \\ 1 & x_{21} & x_{22} & x_{23} \\ 1 & x_{31} & x_{32} & x_{33} \\ 1 & x_{41} & x_{42} & x_{43} \end{pmatrix} \quad \mathbf{e} = \begin{pmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \end{pmatrix}$$

The design matrix X. Details of both the experimental design and the observed values of the predictor variables all reside solely in X

### The Sire Model in Matrix Form

The model here is  $y_{ij} = \mu + s_i + e_{ij}$ Consider three sires. Sire 1 has 2 offspring, sire 2 has one and sire 3 has three. The GLM form is

$$\mathbf{y} = \begin{pmatrix} y_{11} \\ y_{12} \\ y_{21} \\ y_{31} \\ y_{32} \\ y_{33} \end{pmatrix}, \quad \mathbf{X} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \end{pmatrix} \quad \boldsymbol{\beta} = \begin{pmatrix} \mu \\ s_1 \\ s_2 \\ s_3 \end{pmatrix}, \quad \text{and} \quad \mathbf{e} = \begin{pmatrix} e_{11} \\ e_{12} \\ e_{21} \\ e_{31} \\ e_{32} \\ e_{33} \end{pmatrix}$$

Still need to specify covariance structure of the residuals. For example, could be common-family effects that make some correlated.

## In-class Exercise

Suppose you measure height and sprint speed for five individuals, with heights (x) of 9, 10, 11, 12, 13 and associated sprint speeds (y) of 60, 138, 131, 170, 221

1) Write in matrix form (i.e, the design matrix X and vector  $\beta$  of unknowns) the following models

2) Using the X and y associated with these models, compute the OLS BLUE,  $\beta = (X^TX)^{-1}X^Ty$  for each

# Rank of the design matrix

- With n observations and p unknowns, X is an  $n \times p$  matrix, so that  $X^TX$  is  $p \times p$
- Thus, at most X can provide unique estimates for up to p < n parameters</li>
- The rank of X is the number of independent rows of X. If X is of full rank, then rank = p
- A parameter is said to be estimable if we can provide a unique estimate of it. If the rank of X is k < p, then exactly k parameters are estimable (some as linear combinations, e.g.  $\beta_1$ -3 $\beta_3$  = 4)
- if  $det(X^TX) = 0$ , then X is not of full rank
- Number of nonzero eigenvalues of X<sup>T</sup>X gives the rank of X.

# Experimental design and X

- The structure of X determines not only which parameters are estimable, but also the expected sample variances, as  $Var(\beta) = k (X^TX)^{-1}$
- Experimental design determines the structure of X before an experiment (of course, missing data almost always means the final X is different form the proposed X)
- Different criteria used for an optimal design. Let  $V = (X^TX)^{-1}$ . The idea is to chose a design for X given the constraints of the experiment that:
  - A-optimality: minimizes tr(V)
  - D-optimality: minimizes det(V)
  - E-optimality: minimizes leading eigenvalue of V

# Ordinary Least Squares (OLS)

When the covariance structure of the residuals has a certain form, we solve for the vector  $\beta$  using OLS If residuals follow a MVN distribution, OLS = ML solution

If the residuals are homoscedastic and uncorrelated,  $\sigma^2(e_i) = \sigma_e^2$ ,  $\sigma(e_i,e_j) = 0$ . Hence, each residual is equally weighted,

Sum of squared residuals can be written as

$$\sum_{i=1}^{n} \widehat{e}_{i}^{2} = \widehat{\mathbf{e}}^{T} \widehat{\mathbf{e}} = (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^{T} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$$

Predicted value of the y's

# Ordinary Least Squares (OLS)

$$\sum_{i=1}^{n} \widehat{e}_{i}^{2} = \widehat{\mathbf{e}}^{T} \widehat{\mathbf{e}} = (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^{T} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$$

Taking (matrix) derivatives shows this is minimized by

$$\beta = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$$

This is the OLS estimate of the vector  $\beta$ 

The variance-covariance estimate for the sample estimates is

$$\mathbf{V}_{\beta} = (\mathbf{X}^T \mathbf{X})^{-1} \sigma_e^2$$

The ij-th element gives the covariance between the estimates of  $\beta_i$  and  $\beta_i$ .

## Sample Variances/Covariances

The residual variance can be estimated as

$$\widehat{\sigma_e^2} = \frac{1}{n - \text{rank}(X)} \sum_{i=1}^n \widehat{e}_i^2$$

The estimated residual variance can be substituted into

$$\mathbf{V}_{\beta} = (\mathbf{X}^T \mathbf{X})^{-1} \sigma_e^2$$

To give an approximation for the sampling variance and covariances of our estimates.

Confidence intervals follow since the vector of estimates  $\sim \text{MVN}(\beta, \mathbf{V}_{\beta})$ 

## Example: Regression Through the Origin

$$y_i = \beta x_i + e_i$$

Here 
$$\mathbf{X} = \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix}$$
  $\mathbf{y} = \begin{pmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{pmatrix}$   $\boldsymbol{\beta} = (\beta)$ 

$$\mathbf{X}^T \mathbf{X} = \sum_{i=1}^n x_i^2 \qquad \mathbf{X}^T \mathbf{y} = \sum_{i=1}^n x_i y_i$$

$$\beta = \left(\mathbf{X}^T \mathbf{X}\right)^{-1} \mathbf{X}^T \mathbf{y} = \frac{\sum x_i y_i}{\sum x_i^2}$$

$$\sigma^2(\beta) = \frac{1}{n-1} \frac{\sum (y_i - \beta x_i)^2}{\sum x_i^2}$$

$$\beta = \left(\mathbf{X}^T \mathbf{X}\right)^{-1} \mathbf{X}^T \mathbf{y} = \frac{\sum x_i y_i}{\sum x_i^2}$$

$$\sigma^2(\beta) = \frac{1}{n-1} \frac{\sum (y_i - \beta x_i)^2}{\sum x_i^2}$$

$$\sigma_e^2(\beta) = \frac{1}{n-1} \frac{\sum (y_i - \beta x_i)^2}{\sum x_i^2}$$

$$\sigma_e^2(\beta) = \frac{1}{n-1} \sum (y_i - \beta x_i)^2$$

$$\sigma_e^2 = \frac{1}{n-1} \sum_i (y_i - \beta x_i)^2$$

# Polynomial Regressions

GLM can easily handle any function of the observed predictor variables, provided the parameters to estimate are still linear, e.g.  $Y = \alpha + \beta_1 f(x) + \beta_2 g(x) + \cdots + e$ 

### Quadratic regression:

$$y_i = \alpha + \beta_1 x_i + \beta_2 x_i^2 + e_i$$

$$\boldsymbol{\beta} = \begin{pmatrix} \alpha \\ \beta_1 \\ \beta_2 \end{pmatrix} \quad \mathbf{X} = \begin{pmatrix} 1 & x_1 & x_1^2 \\ 1 & x_2 & x_2^2 \\ \vdots & \vdots & \vdots \\ 1 & x_n & x_n^2 \end{pmatrix}$$

## Interaction Effects

Interaction terms (e.g.  $sex \times age$ ) are handled similarly

$$y_i = \alpha + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i1} x_{i2} + e_i$$

$$\boldsymbol{\beta} = \begin{pmatrix} \alpha \\ \beta_1 \\ \beta_2 \\ \beta_3 \end{pmatrix} \quad \mathbf{X} = \begin{pmatrix} 1 & x_{11} & x_{12} & x_{11}x_{12} \\ 1 & x_{21} & x_{22} & x_{21}x_{22} \\ \vdots & \vdots & \vdots & \vdots \\ 1 & x_{n1} & x_{n2} & x_{n1}x_{n2} \end{pmatrix}$$

With  $x_1$  held constant, a unit change in  $x_2$  changes y by  $\beta_2 + \beta_3 x_1$  (i.e., the slope in  $x_2$  depends on the current value of  $x_1$ )

Likewise, a unit change in  $x_1$  changes y by  $\beta_1 + \beta_3 x_2$ 

# The GLM lets you build your own model!

- Suppose you want a quadratic regression forced through the origin where the slope of the quadratic term can vary over the sexes
- $Y_i = \beta_1 x_i + \beta_2 x_i^2 + \beta_3 s_i x_i^2$
- $s_i$  is an indicator (0/1) variable for the sex (0=male, 1=female).
  - Male slope =  $\beta_2$ ,
  - Female slope =  $\beta_2 + \beta_3$

## Fixed vs. Random Effects

In linear models are are trying to accomplish two goals: estimation the values of model parameters and estimate any appropriate variances.

For example, in the simplest regression model,  $y = \alpha + \beta x + e$ , we estimate the values for  $\alpha$  and  $\beta$  and also the variance of e. We, of course, can also estimate the  $e_i = y_i - (\alpha + \beta x_i)$ 

Note that  $\alpha/\beta$  are <u>fixed constants</u> are we trying to estimate (fixed factors or fixed effects), while the  $e_i$  values are drawn from some probability distribution (typically Normal with mean 0, variance  $\sigma^2_e$ ). The  $e_i$  are random effects.

This distinction between fixed and random effects is extremely important in terms of how we analyzed a model.

If a parameter is a fixed constant we wish to estimate, it is a fixed effect. If a parameter is drawn from some probability distribution and we are trying to make inferences on either the distribution and/or specific realizations from this distribution, it is a random effect.

We generally speak of estimating fixed factors and predicting random effects.

"Mixed" models contain both fixed and random factors

$$y = Xb + Zu + e$$
,  $u \sim MVN(0,R)$ ,  $e \sim MVN(0,\sigma_e^2I)$ 

Key: need to specify covariance structures for MM 24

## Example: Sire model

$$y_{ij} = \mu + s_i + e_{ij}$$

Here  $\mu$  is a fixed effect, e a random effect

Is the sire effects fixed or random?

It depends. If we have (say) 10 sires, if we are ONLY interested in the values of these particular 10 sires and don't care to make any other inferences about the population from which the sires are drawn, then we can treat them as fixed effects. In the case, the model is fully specified the covariance structure for the residuals. Thus, we need to estimate  $\mu$ ,  $s_1$  to  $s_{10}$  and  $\sigma^2_e$ , and we write the model as  $y_{ij} = \mu + s_i + e_{ij}$ ,  $\sigma^2(e) = \sigma^2_e$  I

$$y_{ij} = \mu + s_i + e_{ij}$$

Conversely, if we are not only interested in these 10 particular sires but also wish to make some inference about the population from which they were drawn (such as the additive variance, since  $\sigma_A^2 = 4\sigma_{s_i}^2$ ), then the  $s_i$  are random effects. In this case we wish to estimate  $\mu$  and the variances  $\sigma^2$  and  $\sigma^2$ . Since  $2s_i$  also estimates (or predicts) the breeding value for sire i, we also wish to estimate (predict) these as well. Under a Random-effects interpretation, we write the model as

 $y_{ij} = \mu + s_i + e_{ij}$ ,  $\sigma^2(e) = \sigma_e^2 I$ ,  $\sigma^2(s) = \sigma_A^2 A$ 

# Generalized Least Squares (GLS)

Suppose the residuals no longer have the same variance (i.e., display heteroscedasticity). Clearly we do not wish to minimize the unweighted sum of squared residuals, because those residuals with smaller variance should receive more weight.

Likewise in the event the residuals are correlated, we also wish to take this into account (i.e., perform a suitable transformation to remove the correlations) before minimizing the sum of squares.

Either of the above settings leads to a GLS solution in place of an OLS solution.

In the GLS setting, the covariance matrix for the vector e of residuals is written as R where  $R_{ii} = \sigma(e_i,e_i)$ 

The linear model becomes  $y = X\beta + e$ , cov(e) = R

The GLS solution for  $\beta$  is

$$\mathbf{b} = \left(\mathbf{X}^T \mathbf{R}^{-1} \mathbf{X}\right)^{-1} \mathbf{X}^T \mathbf{R}^{-1} \mathbf{y}$$

The variance-covariance of the estimated model parameters is given by

$$\mathbf{V_b} = \left(\mathbf{X}^T \mathbf{R}^{-1} \mathbf{X}\right)^{-1} \sigma_e^2$$

## Example

One common setting is where the residuals are uncorrelated but heteroscedastic, with  $\sigma^2(e_i) = \sigma^2_e/w_i$ .

For example, sample i is the mean value of  $n_i$  individuals, with  $\sigma^2(e_i) = \sigma_e^2/n_i$ . Here  $w_i = n_i$ 

$$\mathbf{R} = \text{Diag}(w_1^{-1}, w_2^{-1}, \dots, w_n^{-1})$$

Consider the model  $y_i = \alpha + \beta x_i$ 

$$\boldsymbol{\beta} = \begin{pmatrix} \alpha \\ \beta \end{pmatrix} \qquad \mathbf{X} = \begin{pmatrix} 1 & x_1 \\ \vdots & \vdots \\ 1 & x_n \end{pmatrix}$$

#### Here

$$\mathbf{R}^{-1} = \mathrm{Diag}(w_1, w_2, \dots, w_n)$$

### giving

$$\mathbf{X}^{T}\mathbf{R}^{-1}\mathbf{y} = w \begin{pmatrix} \overline{y}_{w} \\ \overline{xy}_{w} \end{pmatrix} \qquad \mathbf{X}^{T}\mathbf{R}^{-1}\mathbf{X} = w \begin{pmatrix} 1 & \overline{x}_{w} \\ \overline{x}_{w} & \overline{x^{2}}_{w} \end{pmatrix}$$

#### where

$$w = \sum_{i=1}^{n} w_i, \quad \overline{x_w} = \sum_{i=1}^{n} \frac{w_i x_i}{w}, \quad \overline{x^2}_w = \sum_{i=1}^{n} \frac{w_i x_i^2}{w}$$
$$\overline{y_w} = \sum_{i=1}^{n} \frac{w_i y_i}{w}, \quad \overline{xy_w} = \sum_{i=1}^{n} \frac{w_i x_i y_i}{w}$$

### This gives the GLS estimators of $\alpha$ and $\beta$ as

$$a = \overline{y}_w - b\overline{x}_w$$

$$b = \frac{\overline{x}\overline{y}_w - \overline{x}_w \, \overline{y}_w}{\overline{x}^2_w - \overline{x}_w^2}$$

Likewise, the resulting variances and covariance for these estimators is

$$\sigma^{2}(a) = \frac{\sigma_{e}^{2} \cdot \overline{x^{2}}_{w}}{w \left(x^{2}_{w} - \overline{x}_{w}^{2}\right)}$$

$$\sigma^2(b) = \frac{\sigma_e^2}{w(\overline{x^2}_w - \overline{x}_w^2)}$$

$$\sigma(a,b) = \frac{-\sigma_e^2 \, \overline{x}_w}{w \, (\overline{x^2}_w - \overline{x}_w^2)}$$

## Chi-square and F distributions

Let  $U_i \sim N(0,1)$ , i.e., a unit normal

The sum  $U_1^2 + U_2^2 + \cdots + U_k^2$  is a chi-square random variable with k degrees of freedom

Under appropriate normality assumptions, the sums of squares that appear in linear models are also chi-square distributed. In particular,

$$\sum_{i=1}^{n} (x_i - \overline{x})^2 \sim \chi_{n-1}^2$$

The ratio of two chi-squares is an F distribution

In particular, an F distribution with k numerator degrees of freedom, and n denominator degrees of freedom is given by

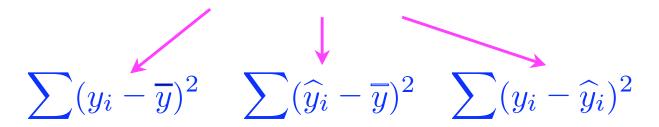

$$\frac{\chi_k^2/k}{\chi_n^2/n} \sim F_{k,n}$$

Thus, F distributions frequently arise in tests of linear models, as these usually involve ratios of sums of squares.

## Sums of Squares in linear models

The total sums of squares SST of a linear model can be written as the sum of the error (or residual) sum of squares and the model (or regression) sum of squares

$$SS_T = SS_M + SS_E$$

 $r^2$ , the coefficient of determination, is the fraction of variation accounted for by the model

$$r^2 = \frac{SS_M}{SS_T} = 1 - \frac{SS_E}{SS_T}$$

### Sums of Squares are quadratic products

$$SS_T = \sum_{i=1}^{n} (y_i - \overline{y})^2 = \sum_{i=1}^{n} y_i^2 - \overline{y}^2 = \sum_{i=1}^{n} y_i^2 - \frac{1}{n^2} \left( \sum_{i=1}^{n} y_i \right)^2$$

We can write this as a quadratic product as

$$SS_T = \mathbf{y}^T \mathbf{y} - \frac{1}{n} \mathbf{y}^T \mathbf{J} \mathbf{y} = \mathbf{y}^T \left( \mathbf{I} - \frac{1}{n} \mathbf{J} \right) \mathbf{y}$$

Where J is a matrix all of whose elements are 1's

$$SS_{E} = \sum_{i=1}^{n} (y_{i} - \hat{y}_{i})^{2} = \sum_{i=1}^{n} \hat{e}_{i}^{2}$$

$$SS_{E} = \mathbf{y}^{T} \left( \mathbf{I} - \mathbf{X} \left( \mathbf{X}^{T} \mathbf{X} \right)^{-1} \mathbf{X}^{T} \right) \mathbf{y}$$

$$SS_{M} = SS_{T} - SS_{E} = \mathbf{y}^{T} \left( \mathbf{X} \left( \mathbf{X}^{T} \mathbf{X} \right)^{-1} \mathbf{X}^{T} - \frac{1}{n} \mathbf{J} \right) \mathbf{y}$$
35

# Expected value of sums of squares

- In ANOVA tables, the E(MS), or expected value of the Mean Squares (scaled SS or Sum of Squares), often appears
- This directly follows from the quadratic product. If  $E(x) = \mu$ , Var(x) = V, then
  - $-E(x^TAx) = tr(AV) + \mu^TA\mu$

### Hypothesis testing

Provided the residual errors in the model are MVN, then for a model with n observations and p estimated parameters,

$$\frac{\mathrm{SS}_E}{\sigma_e^2} \sim \chi_{n-p}^2$$

Consider the comparison of a full (p parameters) and reduced (q < p) models, where  $SSE_r$  = error SS for reduced model,  $SSE_f$  = error SS for full model

$$\left(\frac{SS_{E_r} - SS_{E_f}}{p - q}\right) / \left(\frac{SS_{E_f}}{n - p}\right) = \left(\frac{n - p}{p - q}\right) \left(\frac{SS_{E_r}}{SS_{E_f}} - 1\right)$$

The difference in the error sum of squares for the full and reduced model provided a test for whether the model fit is the same

This ratio follows an  $F_{p-q,n-p}$  distribution

Does our model account for a significant fraction of the variation?

Here the reduced model is just  $y_i = u + e_i$ 

In this case, the error sum of squares for the reduced model is just the total sum of squares and the F test ratio becomes

$$\left(\frac{n-p}{p-1}\right)\left(\frac{\mathrm{SS}_T}{\mathrm{SS}_{E_f}}-1\right) = \left(\frac{n-p}{p-1}\right)\left(\frac{r^2}{1-r^2}\right)$$

This ratio follows an  $F_{p-1,n-p}$  distribution

# Model diagnostics

- It's all about the residuals
- Plot the residuals
  - Quick and easy screen for outliers
- Test for normality among estimated residuals
  - Q-Q plot
  - Wilk-Shapiro test
  - If non-normal, try transformations, such as log

## OLS, GLS summary

	OLS	GLS
Assumed distribution of residuals	$\mathbf{e} \sim (0, \sigma_e^2  \mathbf{I})$	$\mathbf{e} \sim (0, \mathbf{V})$
Least-squares estimator of $oldsymbol{eta}$	$\widehat{oldsymbol{eta}} = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y}$	$\widehat{\boldsymbol{eta}} = (\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{V}^{-1} \mathbf{y}$
$\mathrm{Var}(\widehat{oldsymbol{eta}})$	$(\mathbf{X}^T\mathbf{X})^{-1}\sigma_e^2$	$(\mathbf{X}^T\mathbf{V}^{-1}\mathbf{X})^{-1}$
Predicted values, $\widehat{\mathbf{y}} = \mathbf{X}\widehat{oldsymbol{eta}}$	$\mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y}$	$\mathbf{X}(\mathbf{X}^T\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}^T\mathbf{V}^{-1}\mathbf{y}$
$Var(\widehat{\mathbf{y}})$	$\mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\sigma_e^2$	$\mathbf{X}(\mathbf{X}^T\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}^T$

### Different statistical models

- GLM = general linear model
  - OLS ordinary least squares: e ~ MVN(0,cI)
  - GLS generalized least squares: e ~ MVN(0,R)
- Mixed models
  - Both fixed and random effects (beyond the residual)
- Mixture models
  - A weighted mixture of distributions
- Generalized linear models
  - Nonlinear functions, non-normality

## Mixture models

- Under a mixture model, an observation potentially comes from one of several different distributions, so that the density function is  $\pi_1\phi_1 + \pi_2\phi_2 + \pi_3\phi_3$ 
  - The mixture proportions  $\pi_i$  sum to one
  - The  $\varphi_i$  represent different distribution, e.g., normal with mean  $\mu_i$  and variance  $\sigma^2$
- Mixture models come up in QTL mapping -- an individual could have QTL genotype QQ, Qq, or qq
  - See Lynch & Walsh Chapter 13
- They also come up in codon models of evolution, were a site may be neutral, deleterious, or advantageous, each with a different distribution of selection coefficients
  - See Walsh & Lynch (volume 2A website), Chapters 10,11 42

# Generalized linear models

The Generalized Linear Model (note the ized ending) takes this a step further by assuming for some monotonic function g, that

$$E[y_i] = g\left(\mu + \sum_{k=1}^n \beta_k x_{ik}\right) \tag{2}$$

In particular, taking the inverse  $g^{-1}$  of the function g returns a linear model, with

$$g^{-1}(E[y_i]) = \mu + \sum_{k=1}^{n} \beta_k x_{ik}$$
 (3)

The function f with the property that expresses the expected value of the response variable as a linear function of the predictor variables, i.e.,

$$f(E[y_i]) = \mu + \sum_{k=1}^{n} \beta_k x_{ik}$$

is called the link function of the particular generalized linear model.

Typically assume non-normal distribution for residuals, e.g., Poisson, binomial, gamma, etc

## Likelihoods for GLMs

Under assumption of MVN,  $x \sim MVN(\beta, V)$ , the likelihood function becomes

$$L(\beta, \mathbf{V} \mid \mathbf{x}) = (2\pi)^{-n/2} |\mathbf{V}|^{-1/2} \exp \left[ -\frac{1}{2} (\mathbf{x} - \beta)^T \mathbf{V}^{-1} (\mathbf{x} - \beta) \right]$$

Variance components (e.g.,  $\sigma_A^2$ ,  $\sigma_e^2$ , etc.) are included in **V** 

REML = restricted maximum likelihood. Method of choice for variance components, as it maximizes that part of the likelihood function that is independent of the fixed effects,  $\beta$ .
